Enzyme-linked immunosorbent assays (ELISA) and immunoblots using either whole-cell lysates of *Borrelia burgdorferi* or an antigenic region of flagellin (41-G) as the antigen were performed, and the abilities of the two assays to detect antibodies to this spirochete in dog, cottontail rabbit, and horse sera were compared. Assays using whole-cell *B. burgdorferi* lysates as the antigen were more sensitive for detecting antibodies. ELISA with 41-G as the antigen were specific for *Borrelia* antibodies but were not as sensitive as the assays with whole-cell lysates coated to the solid phase. Use of recombinant full-length flagellin, rather than 41-G, as the antigen in immunoblots increased the sensitivity of each assay. However, antibodies to other bacterial antigens cross-react with whole flagellin and may account for false-positive results. Antibodies to *B. burgdorferi* outer surface protein A or B were usually undetected when the sera were tested by immunoblotting methods. *Borrelia* lysates or the 41-G antigen may be used in ELISA or immunoblots to document host exposure to this spirochete. The use of 41-G as the antigen may increase the specificity of an assay or help confirm the serologic diagnosis of Lyme borreliosis in dogs, horses, and cottontail rabbits.

Lyme borreliosis is the most common tick-associated disease in the United States (30). The causative agent, *Borrelia burgdorferi*, is mostly transmitted by the bites of ticks in the *Ixodes ricinus* complex and can infect humans and various domesticated animals including dogs and horses (3, 4, 11, 13, 16, 19, 30). The clinical manifestations of disease in both humans and animals may be absent or difficult to discern (15, 23, 30). Signs of disease in dogs, horses, and other animals may include lameness, carditis, or a flu-like illness, but an accurate description of the stages of Lyme borreliosis in wildlife and domesticated animals is still being defined (12, 16, 17, 19, 21, 22, 31).

Serologic testing for antibodies to *B. burgdorferi* may be used to help document infection by this bacterium in wildlife, domesticated animals, and humans (5, 6, 9, 12, 14, 17, 19–23). The current serologic tests, however, are confounded by a lack of sensitivity in early infection and by false-positive results caused by the reactivity of antibodies produced during other infectious or inflammatory diseases to *B. burgdorferi* antigens (1, 18, 20, 25). Much of this work has been elucidated in human Lyme borreliosis, but the principles apply to veterinary diseases as well. Antibodies to the *B. burgdorferi* flagellin develop early during infection and may, therefore, be a good indicator of exposure to this spirochete (2, 5, 9, 10, 14, 30). Flagellin, however, shares epitopes with other infectious agents, such as treponemes and leptospires, and antibodies to flagellin may account for the false-positive reactivity (19, 20).

To develop more-specific reagents for antibodies in diagnostic assays, we have identified immunogenic epitopes of flagellin. We have shown that an epitope of flagellin, containing amino acids 197 to 241 and designated 41-G, reacts with antibodies in human sera (2, 9, 24). Others have also shown that antigenic epitopes in a similar region of flagellin are recognized by sera from patients (27, 28). Serologic tests, including both enzyme-linked immunosorbent assays (ELISA) and immunoblots using 41-G as the antigen appear to be more specific in documenting exposure to *B. burgdorferi* in humans than assays with whole-cell lysates (2, 9, 24). Indeed, Gassmann and coworkers have reported that certain epitopes of flagellin are reactive with animal sera as well (10). The usefulness of whole-cell lysates or 41-G as antigens in assays for diagnosing veterinary Lyme borreliosis, however, needs further study. The purpose of this study was to compare the abilities of ELISA and immunoblots with whole-cell *B. burgdorferi* lysates and an antigenic region of flagellin (41-G) from this spirochete as the antigens to help diagnose Lyme borreliosis in dogs, horses, and cottontail rabbits (*Sylvilagus floridanus*).

**MATERIALS AND METHODS**

**Collection of serum samples.** Blood samples were obtained from horses living in communities with the tick vector *Ixodes scapularis*, formerly known as *Ixodes dammini* (26), in Connecticut, Massachusetts, and New York State (19). Serum samples were also received from veterinarians who drew blood from privately owned dogs of various breeds in southern Connecticut, representing rural, suburban, and urban communities where Lyme borreliosis is prevalent (21, 23). Cottontail rabbits were captured in wooden box traps in New York State and Connecticut. Blood samples were taken from the rabbits, and serum samples were stored at −60°C until antibody analyses could be conducted (22). The sources of positive and negative serum controls for all animal groups have been reported elsewhere (17, 19, 22). The sera used included sera from a New Zealand White rabbit inoculated...
with *B. burgdorferi*, dogs that had antibodies to specific proteins (OspA and p39) of *B. burgdorferi*, and horses that had been exposed to *B. burgdorferi*-infected *I. dammini* and had limb or joint disorders.

**Antigen preparation.** Washed, whole-cell lysates of *B. burgdorferi* (strain 2591), the prototypic strain in our ELISA, were used as previously reported (24). Details on the amplification of the 41-kDa flagellin and outer surface protein A and B (OspA and OspB) genes by the polymerase chain reaction have been described elsewhere (2, 7-10). All recombinant antigens were expressed and purified as glutathione transferase fusion proteins. On the basis of previous serologic analyses, an antigenic region of the *B. burgdorferi* flagellin that contained amino acids 197 to 241 was designated 41-G. This antigen was strongly reactive with human sera (2, 9, 24). We chose the 41-G antigen for testing animal sera because of the encouraging results in serologic analyses of human sera in different laboratories (9, 24). Furthermore, 41-G has limited sequence similarity to the flagellin of *Treponema* spp., such as *Treponema pallidum*, and other bacteria that can cause immune responses in hosts and indirectly contribute to false-positive reactivity in diagnostic tests for Lyme borreliosis (9, 18, 24).

ELISA. To quantitate the concentration of total immunoglobulins to whole-cell lysates of *B. burgdorferi* or the recombinant 41-G antigen, an ELISA was used. Preliminary analyses of positive-control sera revealed that antigen concentrations of 3 and 5 μg of protein per ml were suitable for whole-cell lysate and the 41-G antigen, respectively. Dog, horse, and cottontail rabbit sera were diluted ≥1:160 and screened against both types of antigen in parallel tests on the same immunoplates. Polyvalent horseradish peroxidase-labeled antisera and substrate (2,2'-azino-di-3-ethyl-benzthiazoline sulphonate) were used in all assays. Details on sources and working dilutions of antigens, control sera, and other reagents, methods of determining optical density values for positive results, and procedures for performing ELISA with various mammalian species have been published (19, 22-24).

Each plate contained positive-control sera, affinity-purified glutathione transferase, and phosphate-buffered saline (PBS) to ensure standardization before routine use. Glutathione transferase was included because the 41-G antigen was purified as a glutathione transferase fusion protein.

Tests on specificity were conducted to further evaluate the serum samples and antigens used in ELISA. Reference rabbit antisera to *B. burgdorferi* (homologous antibody titer of ≥1:10,240) or to *Borrelia hermsii* were reanalyzed as previously described (22) against whole-cell lysates of *B. burgdorferi* and screened against recombinant 41-G in parallel ELISAs. In addition, these antisera were tested against homologous and heterologous whole-cell antigens by indirect fluorescent-antibody staining methods to verify reagent activity. Fluorescein-labeled goat anti-rabbit total immunoglobulins were obtained commercially (Grand Island Biological Company, Grand Island, N.Y.) and were diluted in PBS to 1:50. The following antisera were tested: *B. hermsii* (strain HS1 serotype C), *B. burgdorferi* (strain 2591), *T. pallidum*, *Leptospira interrogans* serovar pomona (strain MLS) and *L. interrogans* serovar grippotyphosa (strain SC4397). The sources and methods of preparing antigens and antisera have been reported elsewhere (22).

**Immunobots.** For the immunobots, 1.5 μg of *B. burgdorferi* (strain 297) and 500 ng of a recombinant antigen (41-G, OspA, OspB, or flagellin) were resolved by sodium dodecyl sulfate-polyacrylamide gel electrophoresis using a 12% polyacrylamide gel. Strain 297 of *B. burgdorferi* is the prototypic strain (used in our previous immunoblot assays) and is similar to strain 2591. Proteins were transferred to nitrocellulose sheets, and the nitrocellulose sheets were probed with sera, diluted 1:100 in PBS with 5% bovine serum albumin (BSA) for 1 h. The strips were washed three times with PBS and incubated with horseradish peroxidase-labeled goat antiserum against rabbit, dog, or horse immunoglobulin, either immunoglobulin G (IgG) or IgM (Kirkegaard and Perry, Gaithersburg, Md.), diluted 1:3,000 in PBS with 5% BSA. After being washed in PBS, the sheets were developed using the enhanced chemiluminescence detection system (Amer sham, Arlington Heights, Ill.) and exposed to radioative film.

**RESULTS**

Serum samples from dogs, horses, and cottontail rabbits, collected in regions of Connecticut and New York State where Lyme borreliosis is endemic, were tested for reactivity to *B. burgdorferi* lysates and 41-G by ELISA (Table 1). For the groups of sera that reacted positively in ELISA with whole-cell lysates, antibody titers ranged from 1:160 to 1:40,960. A total of 40 dog serum samples were evaluated. Of the 28 serum samples containing antibodies to whole-cell lysates, 12 (42.9%) reacted with 41-G. Six (28.6%) of 21 horse serum samples reactive in ELISA with whole-cell lysates. One dog serum sample (titer, 1:1,280) and one rabbit serum sample (titer, 1:160) reacted with the 41-G antigen. The remaining specimens were negative when the recombinant antigen was used. In each group of animal sera, the geometric mean antibody titer was higher for sera tested with *B. burgdorferi* lysates than for sera tested with the 41-G antigen.

* Whole-cell lysates (WCL) of B. burgdorferi, recombinant 41-G glutathione transferase fusion protein, and recombinant flagellin glutathione transferase fusion protein were used as antigens.

DISCUSSION

Immunoplates coated with whole-cell lysates of B. burgdorferi can detect antibodies to this spirochete in dogs, horses, and rabbits. Cross-reactivity, however, between B. burgdorferi antigens and antibodies elicited during infection of animals with other bacteria, such as treponemes, or inflammatory disease, may account for false-positive results (1, 18, 25). Cross-reactivity has been documented in human disease and may confound the interpretation of serologic data for domestic animals and wildlife as well.

We performed serologic assays using 41-G, an antigenic region of flagellin, to determine whether this recombinant protein would be more specific and sensitive than whole-cell antigens for detecting antibodies to B. burgdorferi. 41-G has been shown to be a useful reagent in confirming human B. burgdorferi infection by serologic assays (9, 24). If the human and other mammalian immune responses are similar, as indicated previously, then 41-G would be an appropriate diagnostic antigen (10). On the basis of our analyses of animal sera and specificity tests, some animal sera that were reactive with whole-cell B. burgdorferi lysates in ELISA or immunoblots were also positive when 41-G was used. The 41-G antigen appears to be highly specific for Borrelia infection. Antibodies to OspA and OspB, however, were virtually undetected in the sera. This result agrees with our previous data, showing that the OspA and OspB humoral response does not occur until late in human infection (9). Although 41-G might be highly specific for Borrelia infection, the sensitivity of an ELISA using this antigen is not yet optimal.

Several possibilities exist for the current low sensitivity of the assay using 41-G. Immunoglobulins in sera of animals that react with the B. burgdorferi lysate may be cross-reactive antibodies elicited during other infectious or inflammatory diseases—as occurs in human disease. Some of the sera reactive to whole-cell lysates in our study could represent false-negative results. In this case, a specific assay, including 41-G antigen, might reduce the number of false-positive reactions, as previously reported for sera from...
other recombinant *B. burgdorferi* antigens, such as p39, an antigen recognized during human infection, may prove useful in laboratory diagnosis of Lyme borreliosis in animals (29).

The use of recombinant *B. burgdorferi* antigens for the laboratory diagnosis of veterinary Lyme borreliosis must be further explored to be clinically useful. Whole-cell lysates of this spirochete appear to be effective in detecting antibodies in dogs, horses, and rabbits. However, the potential for false-positive reactions may confound test data, as has occurred with serologic results for humans. The 41-G antigen, in particular, may be useful as a diagnostic reagent in ELISA because the specificity of this antigen is greater than that of whole-cell antigens.

ACKNOWLEDGMENTS

We thank Neil Infante and Bonnie Hamid for assistance and are grateful to Russell C. Johnson at the University of Minnesota and Alan G. Barbour of the University of Texas for providing *Leptospira* and *Borrelia* antigens and reference antisera.
