Received 21 January 1998/Returned for modification 12 March 1998/Accepted 21 July 1998

Staphylococcus lugdunensis is being increasingly reported as a pathogen with an outcome resembling that of S. aureus rather than coagulase-negative staphylococci. Recent local isolates exhibited colonial variation that delayed identification and interpretation of clinical significance. Until now previous descriptions have not emphasized colonial variation as an important identifying characteristic of S. lugdunensis.

Since its original description in 1988 (4), Staphylococcus lugdunensis has been reported in over 30 cases of endocarditis. Most reports of S. lugdunensis endocarditis have emphasized the aggressive nature of the infection and the problems associated with its identification. We made an observation (the present study and reference 13) regarding the varying colonial morphology of two invasive isolates of this species, and further data from Royal Brisbane Hospital and Gold Coast Hospital has confirmed this feature. We propose that the characteristic of colonial variation may be a common feature of S. lugdunensis, and increased awareness of this characteristic should be helpful in earlier recognition of the pathogen and appropriate management of the infection.

A 59-year-old man with Down’s Syndrome presented with a 6-week history of lethargy and weight loss and 1 week of rigors. Initial blood tests revealed a raised leukocyte count of 15.7 × 109/liter (reference range, 4.0 × 109 to 11.0 × 109/liter) with 84% neutrophils, a hemoglobin level of 121 g/liter (reference range, 132 to 180 g/liter), a platelet count of 139 × 109/liter (reference range, 150 × 109 to 400 × 109/liter), and an erythrocyte sedimentation rate (ESR) of 61 mm/h (reference range, 1 to 30 mm/h). A creatinine level was 106 mol/liter. A trans-thoracic echocardiogram did not identify any valvular vegetations.

The next day, all four culture bottles contained gram-positive cocci morphologically resembling staphylococci. The results of subscultures on solid media suggested a mixed population of staphylococci. A “sweep” of colonies tested clumping factor negative, suggesting the presence of mixed coagulase-negative staphylococci (CoNS) that might be skin contaminants. On the same day, the blood culture isolate obtained prior to the patient’s admission to our institution was reported as a CoNS by another laboratory.

After 7 days, the patient’s renal function gradually improved after plateaueing at a creatinine level of 626 μmol/liter. A trans-esophageal echocardiogram revealed a probable vegetation at the bifurcation of the pulmonary artery and a probable patent ductus arteriosus. In conjunction with the final identification of the blood culture isolate as S. lugdunensis in four out of four culture bottles, a diagnosis of endocarditis was made. The next day, all four culture bottles contained gram-positive cocci. A “sweep” of colonies tested clumping factor negative, suggesting the presence of mixed coagulase-negative staphylococci (CoNS) that might be skin contaminants. On the same day, the blood culture isolate obtained prior to the patient’s admission to our institution was reported as a CoNS by another laboratory.

All four blood samples (cultured in BacT/Alert FAN [Organon Teknika Corporation, Durham, N.C.] aerobic and anaerobic bottles) collected at presentation (before antibiotic administration) yielded gram-positive cocci in clusters that...
FIG. 1. Postmortem specimen of the patient in the present study. Vegetations on the pulmonary artery are shown. The larger vegetation (V) measures 12 mm in its greatest dimension. The smaller vegetation measures 10 mm in its greatest dimension and is situated around the orifice of the patent ductus arteriosus (arrow).

FIG. 2. Marked colonial variation suggestive of mixed culture. Shown is a primary subculture of a positive blood culture (subcultured on chocolate agar) after overnight incubation at 35°C in 5% CO₂.

were catalase positive, consistent with staphylococci. The results of subcultures on solid media (chocolate agar [Oxoid GC agar base with growth supplement; Unipath Ltd., Basingstoke, United Kingdom] and horse blood agar) suggested a mixed population of staphylococci, with at least two different colonial morphologies evident from each blood culture (Fig. 2). Four single-colony subcultures of differing colonial morphotypes also produced colony variations that persisted in three serial subcultures of single-colony picks. All four strains tested gave identical reactions and susceptibility results. Clumping factor (coagulase rabbit plasma with EDTA; BBL Becton Dickinson, Cockeysville, Md.) was not present; the STAPH-A-LEX latex agglutination (Trinity Laboratories Inc., Raleigh, N.C.) and the tube coagulase tests were negative. The RBH-STAPH system that utilizes Rosco diagnostic tablets and susceptibilities to antibiotics for identification of staphylococci (11) showed the isolate to be furazolidone susceptible, desferrioxamine resistant, novobiocin susceptible, $\alpha$-pyrrolidonyl-beta-napthylamide (PYR) positive, polymyxin resistant, and resistant to bacitracin (10 U); to exhibit a zone of inhibition with a diameter of <30 mm around the fosfomycin tablet; and to be ornithine decarboxylase (ODC) positive. These results were consistent with those for $S.\ lugdunensis$. The ID32 STAPH identification system (bioMérieux Vitek Inc., Hazelwood, Mo.) gave an identification profile of 56311460, consistent with a 99.9% positive identification of $S.\ lugdunensis$, with the key reactions being positive results for ODC, trehalose, and PYR. Susceptibility testing performed by disk diffusion (according to guidelines of the National Committee on Clinical Laboratory Standards [9]) showed the isolate to be susceptible to penicillin, oxacillin, methicillin, and vancomycin. The isolate was susceptible to all antimicrobial agents in the Vitek GPS-IX card test (bioMérieux Vitek Inc.) and was not a $\beta$-lactamase producer (when growth at the margin of the zone of inhibition around the penicillin disk was used to inoculate a nitrocefin disk [Cefinase; BBL Becton Dickinson] and inspected for chromogenic change for up to 1 h after inoculation). A nested PCR using primers specific for the $S.\ aureus$ thermonuclease gene (nuc) and primers for the mecA gene encoding penicillin-binding protein 2a (1) was negative for both the nuc and mecA genes. The blood culture isolate reported as a CoNS by another laboratory was sent to our laboratory for confirmation of its identification. It gave results identical to those of our isolate in all tests, thus proving it was $S.\ lugdunensis$.

This case adds to the growing literature of serious invasive $S.\ lugdunensis$ infections. Most reports of $S.\ lugdunensis$ infections comment on the problems in identifying this CoNS since it often gives positive results for clumping factor and other rapid agglutination test results suggestive of $S.\ aureus$. Some automated identification systems are unable to identify $S.\ lugdunensis$ due to insufficient discriminatory biochemical reactions (especially insufficient ODC) or an inadequate database (6, 12, 13). $S.\ lugdunensis$ appears to be an aggressive pathogen; similar to $S.\ aureus$, it causes an aggressive form of endocarditis with a poor clinical outcome. Including this case, there have been 34 cases of $S.\ lugdunensis$ endocarditis reported; of the patients involved in these cases, 19 (of which 7 died) had valve replacement surgery, and 13 (of which 11 died) did not have surgery. Reports on the remaining two patients did not indicate whether they had valvular surgery or not; one died, and the outcome of the other was not given. The poor outcomes of $S.\ lugdunensis$ endocarditis are in marked contrast to the better outcome generally associated with endocarditis caused by other CoNS species (2, 7, 11, 12).

We believe that previous studies of $S.\ lugdunensis$ infections may have underreported the characteristic of colony variation seen in this species. The original description of the species (4) and only three other reports have described colony variation in $S.\ lugdunensis$ isolates (3, 5, 6). The initial description of the species mentioned colony variation for 3 of the 11 strains reported, so different colony morphotypes may not be a consistent feature of the species. However, we suspect that other reports may not have mentioned colony variation. This is likely, since the feature was omitted in a previous report from Royal Perth Hospital (13).
Isolates of CoNS species collected from Royal Brisbane Hospital and Gold Coast Hospital exhibit different colony morphology characteristics depending on the species and the duration of incubation and subculture (Table 1). A summary of the findings is as follows. (i) S. lugdunensis, S. capitis, and S. hominis have a significant percentage of isolates with mixed morphotypes on both horse and sheep blood agar. Other CoNS species have a lower percentage of mixed morphotypes or no colonial variation at all. (ii) Colony variation essentially disappears for S. capitis and S. hominis after extended incubation or subculture. Mixed morphotypes were noted to be more persistent through incubation and subculture in S. lugdunensis strains. (iii) Preceding antimicrobial therapy may play a role in producing colony variation in S. lugdunensis (although in the present case, antimicrobials were not administered before the blood samples from which S. lugdunensis was isolated were collected). Insufficient clinical information regarding preceding antimicrobial exposure was collected for other CoNS species exhibiting colony variation.

We would be interested to learn whether previous authors have noted colony variations in their S. lugdunensis isolates but did not report it. We wish to draw attention to this characteristic in order to facilitate the rapid diagnosis of S. lugdunensis infections. It is hoped that quicker recognition of this species will lead to earlier administration of appropriate therapy with a better outcome (6, 8).

We thank Marsali Newman and Cecily Metcalf for the postmortem specimens and descriptions. We also thank the Medical Illustrations Department of Royal Perth Hospital for excellent photographic work.
