A Longitudinal Case Series Description of Meningitis Due to
Streptococcus gallolyticus subsp. pasteurianus in Infants

Streptococcus gallolyticus subsp. pasteurianus, previously known as Streptococcus bovis biotype II.2, is known to cause multiple infectious complications, including bacterial meningitis, in adults. Only sporadic individual case reports have identified this pathogen as a cause of meningitis in infants. This study is the first to longitudinally document S. gallolyticus subsp. pasteurianus as a cause of meningitis in four epidemiologically unrelated infants less than 2 weeks of age. The 16S rRNA gene sequences of all 4 isolates were identical, and further were identical to 3 central nervous system (CNS) strains (two adults and one child) reported in existing literature. S. gallolyticus subsp. pasteurianus is an increasingly recognized cause of meningitis and bacteremia in the newborn period, and it merits further study with respect to etiology of infection.

**CASE REPORTS**

Patient 1. A full-term male infant was born via spontaneous vaginal delivery after a pregnancy complicated by a maternal urinary tract infection with an unknown pathogen during the month prior to delivery, as well as a maternal stray-cat bite 1 week prior to delivery. He presented at 13 days of age with congestion, increased work of breathing, and increased sleepiness for 1 day (Table 1). He did not exhibit fever at presentation. Initial laboratory values included a complete blood count (CBC), with a white blood cell (WBC) count of 6,570/mm³, with 37% neutrophils, 33% lymphocytes, 23% monocytes, and 3% eosinophils, a hemoglobin level of 17 g/dl, and a platelet count of 382,000/mm³. Cerebrospinal fluid (CSF) showed no bacterial growth, though the CSF exhibited pleocytosis, 23% monocytes, and 3% eosinophils, a hemoglobin level of 17 g/dl, and a platelet count of 382,000/mm³. Cerebrospinal fluid (CSF) revealed a glucose level of 35 mg/dl, a protein level of 60 mg/dl, a red blood cell (RBC) count of 23/mm³, and a WBC count of 13/mm³. CSF Gram staining exhibited no organisms and rare WBCs. He received intravenous (IV) ampicillin and IV cefotaxime empirically. On hospital day 2, the CSF culture grew Gram-negative rods and gamma-hemolytic streptococcus, which were identified on hospital day 4 as Klebsiella oxytoca and S. gallo-
lyticus subsp. pasteurianus. The patient underwent a repeat lumbar puncture on hospital day 4 due to development of emesis and diarrhea, and as the treating physician desired to assess the CSF WBC trend, since the original sample of 13/mm³ was within the normal range for age. Repeat CSF cultures on hospital day 4 showed no bacterial growth, though the CSF exhibited pleocytosis suggestive of infection, with a WBC count of 33/mm³. Herpes simplex virus (HSV) and enterovirus PCR testing (PCR) of the first CSF specimen were negative. After discontinuation of the ampicillin on hospital day 4, the patient was successfully treated with 16 total days of cefotaxime at 300 mg/kg/day, divided and administered every 6 h. Bilateral auditory brainstem response (ABR) evaluation of hearing at discharge revealed no evidence of hearing loss.

Patient 2. A full-term female infant was born via induced vaginal delivery after a pregnancy complicated by late prenatal care

and maternal tobacco abuse. She presented at 5 days of age with fever and seizure-like activity for 1 day, which consisted of bilateral eye fluttering movements and upper extremity tremors (Table 1). She received an initial loading dose of phenobarbital. Blood, urine, and CSF cultures were obtained. Initial CBC values included a WBC count of 3,490/mm³, with 23% neutrophils, 32% lymphocytes, and 4% monocytes, along with a platelet count of 224,000/mm³. Initial CSF studies included a glucose level of 65 mg/dl, an RBC count of 34,650/mm³, and a WBC count of 4,470/mm³. HSV PCR was negative. The patient was initially given two glucose boluses, and ampicillin and gentamicin were administered 2.5 h and 1.5 h before the lumbar puncture, respectively. Vancomycin was added on hospital day 1 when Gram stain of the CSF showed Gram-positive cocci in chains and pairs. Gentamicin was discontinued on hospital day 2. Cefotaxime was added on hospital day 3 when the organism, isolated in the blood and CSF, was identified as presumptive streptococcal species. The vancomycin was discontinued on hospital day 4, when the isolate was identified as *S. galolyticus* subsp. *pasteurianus*. Cefotaxime was continued along with ampicillin until hospital day 6, when the cefotaxime was discontinued at the request of the Infectious Diseases team. Ampicillin was discontinued for a total of 16 days, or 14 days from the first negative blood culture, with the dose of ampicillin at 300 mg/kg/day IV divided every 8 h. Bilateral ABR at discharge and at a follow-up evaluation 1 month after discharge revealed no deficiencies.

### Patient 4
A postterm male was born via spontaneous vaginal delivery after a pregnancy complicated only by maternal hyperemesis gravidarum. Delivery history was significant for prolonged maternal rupture of membranes prior to delivery, lasting approximately 13 h. Meconium staining was observed at birth, but the patient did not suffer any adverse effects.

The patient presented at 5 days of life with fever, rhinorrhea, and fussiness for 1 day (Table 1). Upon presentation to the emergency department, blood, urine, and CSF cultures were obtained. Initial CBC showed a WBC count of 25,740/mm³, with 23% neutrophils, 22% banded neutrophils, 31% lymphocytes, 14% monocytes, and 7% eosinophils, along with a hemoglobin level of 16.2 mg/dl; a platelet count was not performed. Initial CSF studies showed a glucose level of less than 20 mg/dl, a protein level of 234 mg/dl, an RBC count of 25,100/mm³, and a WBC count of 9,700/mm³. Enterovirus PCR of the CSF was negative. He was placed on ampicillin and cefotaxime. A Gram stain of the CSF exhibited Gram-positive cocci in pairs, and ampicillin was changed to vancomycin therapy. On hospital day 2, the CSF culture and blood culture both revealed evidence of gamma-hemolytic streptococci, not pneumococci or enterococci. On hospital day 3, the organism isolated from the blood and CSF was identified as *S. galolyticus* subsp. *pasteurianus*. Vancomycin was discontinued on hospital day 3, when susceptibilities of the isolate were determined. Of note, this *S. galolyticus* subsp. *pasteurianus* isolate was intermediately resistant to penicillin, with a MIC of 0.19 µg/ml. The patient received 14 total days of IV cefotaxime, at 300 mg/kg/day, divided and administered every 6 h. Bilateral ABR at discharge and at a

follow-up 1 month after hospital discharge showed no deficiencies.

**MATERIALS AND METHODS**

Patient data, including patient histories, physical examination findings, daily inpatient progress notes, laboratory findings, imaging findings, medication reconciliation information, discharge information, and follow-up outpatient appointment data, were collected retrospectively using the computerized medical record system at Children’s Mercy Hospitals and Clinics (Kansas City, MO). Study accession numbers were used to pull frozen *S. gallolyticus* subsp. *pasteurianus* isolates originally isolated from cerebrospinal fluid or blood. All specimens were obtained from four subjects who were less than 2 weeks old at presentation. Dates of patient visits ranged from 9 November 2008 through 14 July 2010. Meningitis was defined as the presence of cerebrospinal fluid pleocytosis (>30 white blood cells/mm³) in addition to the growth of *S. gallolyticus* subsp. *pasteurianus* from cerebrospinal fluid culture. Three of the four patients also presented with bacteremia, defined as isolation of *S. gallolyticus* subsp. *pasteurianus* from blood culture.

Microbiologic data for each isolate, including identification and antimicrobial susceptibility patterns for penicillin, vancomycin, and cefotaxime against *S. gallolyticus* subsp. *pasteurianus*, were collected from computerized records. The organisms were identified with a Vitek 2 (bio-Mérieux, Inc.) system, and the MICs were obtained by Etest susceptibility testing.

Approximately the first 500 bases (positions 20 to 510) of the 16S rRNA gene sequence of each strain were obtained by standard methods. Electrophoretograms were analyzed by the MicroSeq program (Applied Biosystems, Foster City, CA). The resulting 16S rRNA sequences were compared with sequences in several databases, including a database consisting of in-house strains, the MicroSeq database, and the public National Center for Biotechnology Information (NCBI) database. An analysis of our four strains, as well as type strains and *S. gallolyticus* subsp. *pasteurianus* central nervous system (CNS) isolates previously reported, showed that all had a T in the 182 position and a C in the 238 position as the only and defining differences from *S. gallolyticus* subsp. *gallolyticus* (2, 4, 5). A dendrogram was generated by the weighted-pair algorithm for constructing phylogenetic trees (Fig. 1).

**RESULTS**

Of the four patients with *S. gallolyticus* subsp. *pasteurianus* meningitis, three had concurrent bacteremia with this pathogen. Patient 1 was coinfected with *Klebsiella oxytoca* in the CSF but did not exhibit bacteremia with either organism. CSF pleocytosis was initially observed in three of four infants (average, 1,956 WBCs/mm³; range, 13 to 4,470 WBCs/mm³), while the serum WBC count was low to low-normal in three of the four patients. The average age of the patients at presentation was 6.25 days (range, 2 to 13 days). Three patients were male, and one was female.

Two of the four infants presented with fever, while two presented with seizure or seizure-like activity. Two of four subjects also presented with congestion and rhinorrhea.

MIC values and susceptibilities to penicillin, cefotaxime, and vancomycin were reported for each isolate. For penicillin, three of the four isolates were reported as susceptible, each with a MIC of 0.125 µg/ml. The fourth isolate was reported as immediately resistant to penicillin, with a MIC of 0.19 µg/ml. Each isolate was reported as susceptible to cefotaxime, with all four having MICs of 0.25 µg/ml. All isolates were reported as susceptible to vancomycin, with MICs of 0.75 µg/ml, 0.75 µg/ml, 0.5 µg/ml, and 0.38 µg/ml.

**DISCUSSION**

*S. gallolyticus*, subsp. *pasteurianus*, formerly known as *S. bovis* biotype II.2, was previously described in three individual case reports as a cause of neonatal meningitis and/or bacteremia. In 2006, a cluster of five preterm infants in a neonatal intensive care unit in France were diagnosed as having bacteremia secondary to *S. gallolyticus* subsp. *pasteurianus*. Four of five isolates were genetically identical to each other, with the fifth isolate closely resembling the other four (7). The etiology of this outbreak was postulated to be environmental contamination followed by transient hand carriage by a staff member; therefore, these infections were likely the result of one index case, followed by a breakdown in infection control measures.

In contrast, our series longitudinally evaluated cases of meningitis with or without associated bacteremia due to *S. gallolyticus* subsp. *pasteurianus*. The cases were unrelated with respect to epidemiology and time frame, having occurred between 2008 and 2010. The 16S rRNA gene sequences of all four isolates were identical, and furthermore, they were identical to the sequences of three CNS strains (from two adults and one child) reported previously, as well as the type strain of *S. gallolyticus* subsp. *pasteurianus* (4, 5). One of the isolates exhibited intermediate resistance to penicillin, with a MIC of 0.19 µg/ml. The prognostic outlook for this patient was not different from that of the other three patients. The isolate that was intermediately resistant to penicillin was the most recently reported of the four listed above. Whether this intermediate resistance is an anomaly or whether this is the beginning of a trend for *S. gallolyticus* subsp. *pasteurianus* remains to be seen. All four of our patients were successfully treated with a minimum of 14 days of IV ampicillin or IV cefotaxime.

The mother of patient 3 had confirmed contact with multiple
chickens that had died within 1 week prior to the birth of the patient. S. bovis species are a known cause of septicemia and sudden death in fowl, including pigeons, turkeys, chickens, and goslings (1, 12). This exposure history could be a potential clue to the etiology of this patient’s S. gallolyticus subsp. pasteurianus infection; however, no postmortem testing was performed on the affected chickens.

One of the limitations of this case series is its retrospective nature; namely, mothers were not asked for an in-depth history of illness during pregnancy. Two of the four mothers had regular prenatal care throughout their entire pregnancy, while one had regular follow-up with a midwife. The mother of patient 2 did not receive prenatal care until her third trimester.

S. gallolyticus subsp. pasteurianus has been associated with colonic neoplasia, endocarditis, peritonitis, and chorioamnionitis in adults (8). A recent case report by Sturt et al. describes S. gallolyticus subsp. pasteurianus as the causative agent of meningitis in a 75-year-old male (13). S. bovis is part of normal colonic flora in 10% of healthy subjects. In one study, S. bovis was isolated from 3.4% of normal vaginal secretions (6); however, that study did not identify the S. bovis isolates to the subspecies level. Future studies should focus on rates of maternal colonization and infection with S. gallolyticus subsp. pasteurianus.
