ABSTRACT

Nosocomial Candida bloodstream infections rank among infections with highest mortality rates. A retrospective cohort analysis was conducted at Catholic University Hospital to estimate risk factors for mortality of patients with candidemia. We reviewed records for patients with a Candida bloodstream infection over a 5-year period (January 2000 through December 2004). Two hundred ninety-four patients (42.1% male; mean age ± standard deviation, 65 ± 12 years) were studied. Patients most commonly were admitted with a surgical diagnosis (162 patients [55.1%]), had a central venous catheter (213 [72.4%]), cancer (118 [40.1%]), or diabetes (58 [19.7%]). One hundred fifty-four (52.3%) patients died within 30 days. Of 294 patients, 168 (57.1%) were infected by Candida albicans, 64 (21.7%) by Candida parapsilosis, 28 (9.5%) by Candida tropicalis, and 26 (8.8%) by Candida glabrata. When fungal isolates were tested for biofilm formation capacity, biofilm production was most commonly observed for isolates of C. tropicalis (20 of 28 patients [71.4%]), followed by C. glabrata (6 of 26 [23.1%]), C. albicans (38 of 168 [22.6%]), and C. parapsilosis (14 of 64 [21.8%]). Multivariable analysis identified inadequate antifungal therapy (odds ratio [OR], 2.35; 95% confidence interval [CI], 1.09 to 5.10; *P* = 0.03), infection with overall biofilm-forming Candida species (OR, 2.33; 95% CI, 1.26 to 4.30; *P* = 0.007), and Acute Physiology and Chronic Health Evaluation III scores (OR, 1.03; 95% CI, 1.01 to 1.15; *P* < 0.001) as independent predictors of mortality. Notably, if mortality was analyzed according to the different biofilm-forming Candida species studied, only infections caused by C. albicans (*P* < 0.001) and C. parapsilosis (*P* = 0.003) correlated with increased mortality. Together with well-established factors, Candida biofilm production was therefore shown to be associated with greater mortality of patients with candidemia, probably by preventing complete organism eradication from the blood.
INTRODUCTION

Nosocomial Candida bloodstream infections (BSIs), with an estimated annual incidence in the United States of 6-10 candidemia episodes per 100,000 population, have become a considerable public health concern (24, 25, 29). Although antifungal treatment appears to reduce mortality and excess hospitalization, the rate of candidemia-attributable mortality remains high (19%-49%) (8, 25). Risk factors for candidemia are associated with modern therapeutics, including broad-spectrum antibiotics, hyperalimentation fluids, cancer chemotherapy, immunosuppressive agents following organ transplantation and indwelling medical devices (17, 19).

Devices such as stents, shunts, prostheses, endotracheal tubes and vascular catheters have been shown to support colonization and biofilm formation by Candida (17). The Candida biofilm lifestyle results in antifungal drug resistance and protection of the fungus from host defenses (20, 32), which carry important clinical repercussions. Device-related infections are difficult to treat, and affected devices often need to be removed (23), which can be hazardous for some patients (39).

Central venous catheters (CVCs) appear to be the most common risk factor for candidemia development in patients without neutropenia or major immunodeficiencies. More than half of BSIs, including candidemia, in intensive care unit (ICU) patients are catheter-related (34, 35).

Parenteral nutrition has also been associated with increased risk of candidemia, particularly in outbreak settings (4). High-glucose media promote the formation of biofilms, particularly of Candida parapsilosis, by enhancing the microorganism's capacity to colonize indwelling CVCs and cause infections in patients receiving intravenous hyperalimentation nutrition (37).

Inadequate antifungal therapy has been shown to be an important predictor of adverse outcome for patients with Candida BSIs (9, 10, 12). Interestingly, two recent studies addressing the effects of delayed treatment for patients with candidemia found that receipt of an antifungal agent >24 h after the blood sample was obtained for culture was associated with an increased risk of mortality (6, 26).

To evaluate risk factors for mortality in hospitalized patients with Candida BSI, a retrospective cohort analysis was conducted at a large Italian University hospital. In particular, we wanted to
determine whether the biofilm formation by *Candida* species, which is intrinsically associated with its infectiousness (3, 32), influenced the clinical outcomes in patients with candidemia.
MATERIALS AND METHODS

Study design, patient population, and data collection. This retrospective cohort study was conducted from January 2000 to December 2004 at the Catholic University Hospital in Rome, Italy, which admits about 60,000 patients annually, with the outcome measure being mortality. Accordingly, two groups of patients (survivors and nonsurvivors) were compared. Eligible patients who were hospitalized during the study period and had at least one positive blood culture for *Candida* species were identified by electronically querying the microbiology laboratory historical database. A standardized case report form was used to extract the following data from the patients' hospital records: age, sex, past medical and surgical history; *Candida* species type and date of culture; presence of a central venous catheter and/or indwelling urinary catheter; total parenteral nutrition administration; immunosuppressive therapy (antineoplastic agents and corticosteroids) within 30 days before infection; degree and duration of neutropenia; APACHE III score (16); type of hospital admission (medical or surgical); location of patient at time of blood culture (ICU or non-ICU), and duration of hospitalization. The type, dose, and duration of antifungal therapy were also identified.

Definitions. Candidemias were defined as hospital-acquired if patients developed positive blood cultures after 48 h of hospital admission (7). Other episodes of candidemia were classified as health-care associated or community-acquired according to definitions suggested by Friedman et al. (5). Criteria for defining healthcare-associated candidemia include: intravenous therapy received at home; wound care or specialized nursing care through a healthcare agency, family, or friends, or self-administered intravenous medical therapy within 30 days prior to onset of candidemia; hospital or hemodialysis clinic attendance or intravenous chemotherapy received within 30 days prior to onset of candidemia; hospitalization in an acute care hospital for 2 or more days within 90 days prior to onset of candidemia; and residence in a nursing home or long-term care facility (5). Candidemia was defined as CVC-related if i) the semiquantitative catheter tip culture yielded more than 15 CFU of the same *Candida* species or ii) simultaneous quantitative cultures showed a ratio
≥5:1 in CFU of blood samples obtained through the catheter and a peripheral vein (23). The outcome variable was defined as survival or death within 30 days of the first documented candidemia episode.

Inadequate therapy of candidemia was defined as the lack of antifungal treatment, administration of antifungal treatment 48 h after having the first positive blood sample for culture, administration of antifungal treatment with isolation of an organism found resistant to the antifungal agent in vitro, or antifungal administration for less than 5 days (1, 2, 26).

**Microbiological methods.** To detect candidemia, blood samples were obtained after sterile disinfection of a peripheral vein or central venous catheter, inoculation into aerobic media and processing by BACTEC 9240 automated system (Becton Dickinson Microbiology Systems). Species identification of *Candida* isolates was performed by micromorphology analysis (40) and biochemical tests (Vitek 2 Yeasts Identification; bioMérieux). For all isolates, minimum inhibitory concentrations (MICs) of amphotericin B, fluconazole, itraconazole, ketoconazole, voriconazole, flucytosine, and caspofungin were determined using the microdilution broth procedure recommended by the Clinical and Laboratory Standards Institute (CLSI) (27). According to published criteria (27, 31), isolates were classified as susceptible, susceptible dose-dependent, or resistant to flucytosine, fluconazole, and voriconazole. Isolates were maintained as frozen stocks and subcultured on Sabouraud dextrose agar plates at 37°C.

**Biofilm formation assays.** Biofilm formation was determined according to well-established protocols (19, 33, 37), with slight modifications. To induce *in vitro* biofilm production by *Candida* isolates, Sabouraud dextrose broth (SDB) containing 8% glucose was used. *Candida albicans* ATCC 90028 and *C. parapsilosis* ATCC 96142 served as controls in each experiment. **Testing of isolates was performed on three different occasions in quadruplicate.** Briefly, organisms were grown for 24 h at 37°C on Sabouraud dextrose agar plates, and saline-washed suspensions of each isolate were used to prepare 3 x 10⁷ CFU/ml inocula in SDB. Each well of polystyrene microtiter plates (Nunclon; Nalgene) was inoculated with 20 µl of yeast cell suspension and 180 µl of SDB.
After 24 h of incubation, planktonic cells were discarded through two washings with 0.15 M phosphate-buffered saline (PBS), and 200 µl of PBS were added to each well. Remaining cells adhering to the plastic surface (biofilm) were quantified using two methods. First, biofilm was measured directly by spectrophotometric readings at 405 nm with a microtiter plate reader (Microplate Reader Model 550; BioRad). The percent transmittance (%T) was calculated by subtracting the %T value for each test sample from the %T value for the reagent blank. Biofilm production by each isolate was scored as either negative (%T <10), 1+ (%T 10 to 20), 2+ (%T 20 to 35), 3+ (%T 35 to 50), or 4+ (%T ≥50). On the basis of these scores, biofilm-producing isolates were further categorized as low-biofilm (1+) or high-biofilm producers (2+, 3+, or 4+). In the second method, biofilm was quantified biochemical using the 2,3-bis(2-methoxy-4-nitro-5 sulfophenyl)-5-[(phenylamino)carbonyl]-2H-tetrazolium hydroxide (XTT; Sigma) reduction assay. In this assay, XTT is reduced by mitochondrial dehydrogenase into a water-soluble formazan product that results in a colorimetric change. A 100-µl aliquot of the XTT salt solution (1 mg/ml in PBS) and 1 µM menadione solution (Sigma; prepared in acetone) were added to each prewashed biofilm and to control wells (for measurement of background XTT-reduction levels). The plates were incubated in the dark at 37°C for 5 h, and the amount of XTT formazan was measured in the microtiter plate reader at 490 nm.

To ascertain whether different yeast isolates in the planktonic phase metabolized XTT in an equal fashion, preliminary experiments were carried out on 80 isolates (35 C. albicans, 25 C. parapsilosis, 10 Candida tropicalis; and 10 Candida glabrata) that were selected from the pool of 294 isolates, as described previously (14).

**Statistical analysis.** Intercooled Stata software, version 8 (Stata Corporation) was used for statistical analysis. Categorical variables were compared using the χ² test or Fisher’s exact test. Continuous variables were compared using the Student’s t test. The relationship between the outcome variable and independent variables were measured by the odds ratios (OR) and their 95% confidence intervals (CI) derived from univariate and multivariable analyses. Variables with
values < 0.2 in the univariate analysis were included in a multivariable logistic regression model. One-way analysis of variance was used to compare the optical density values from individual biofilms. All tests were 2-sided. The significance level was set at $P < 0.05$. 
RESULTS

Species distribution, biofilm production, and in vitro antifungal susceptibility of Candida isolates. The annual distribution of Candida species causing BSIs at our institution was similar between 2000 and 2004 (Figure 1), whereas the proportion of candidemia cases due to biofilm-producing isolates increased from 19% to 47% for non-C. albicans Candida species and remained fairly constant (17% to 20%) for C. albicans (Figure 2). A total of 294 patients with Candida BSIs were evaluated during the study period. Organisms causing infection included C. albicans (57.1%, 168 patients), C. parapsilosis (21.7%, 64 patients), C. tropicalis (9.5%, 28 patients), C. glabrata (8.8%, 26 patients), and other Candida species (2.7%, 8 patients).

Eighty (27.2%) of 294 patients studied were infected by biofilm-forming isolates, as assessed by the %T method. Of these, 20 isolates were high-biofilm producers and 60 low-biofilm producers. Biofilm production by C. albicans was significantly less frequent (22.6%) than that by all other non-C. albicans species (33.3%; P = 0.04). Among the species most commonly isolated from Candida BSIs (C. albicans, C. parapsilosis, C. tropicalis, and C. glabrata), biofilm production was most frequently observed for isolates of C. tropicalis (71.4%, 20 of 28), followed by C. glabrata (23.1%, 6 of 26), C. albicans (22.6%, 38 of 168), and C. parapsilosis (21.8%, 14 of 64). Among biofilm-positive isolates, the highest relative intensity of biofilm formation (%Tbloc >35) was seen for C. tropicalis isolates (30%, 6 of 20), followed by C. parapsilosis (21%, 3 of 14). To confirm the validity of these results, we also measured biofilm growth by using the XTT reduction assay. For all the isolates tested, %T determinations well correlated with XTT absorbance measurements, as seen in Figure 3. These findings were in accord with previous works indicating that XTT assay absorbance readings are proportional to the cellular density in Candida biofilms (13, 21, 33). Importantly, Kuhn et al. (18) reported that, even if the XTT reduction assay remains a valuable tool for examining the yeast biofilm form, its use to make direct comparisons between Candida isolates may be sometimes limited since different Candida species or strains metabolize XTT with different capabilities. This is of particular importance in the absence of correlation with other methods. To
rule out the possibility that the varying ability of different *Candida* species to metabolize tetrazolium salts may account for differences in XTT reduction rates among our isolates, we compared, in preliminary experiments, the XTT activity of 80 randomly selected isolates (from the pool of 294 isolates). Similar values were obtained and no significant difference was noted between the XTT activities of the 80 isolates (data not shown). Therefore, differences seen in the XTT signals from the 294 isolates we tested for biofilm formation were assumed to be a reflection of changes in cell number.

*Candida* species isolates were all found susceptible in vitro to amphotericin B, flucytosine, caspofungin, and, except for *C. glabrata* and *Candida krusei*, to azole antifungal agents. Ten isolates of *C. glabrata* showed decreased susceptibility to fluconazole and voriconazole (MICs, ≥16 µg/ml and ≥2 µg/ml), respectively. Four isolates were classified as resistant (MICs, ≥64 µg/ml and ≥4 µg/ml) to these drugs and 6 isolates as susceptible-dose dependent (MICs, 16 to 32 µg/ml and 2 µg/ml). The two isolates of *C. krusei* were resistant to fluconazole and susceptible to voriconazole.

**Patient demographic, clinical characteristics, and outcomes.** Of 294 patients with *Candida* BSIs (mean age ± SD, 65 ± 12 years; 42.1% male), 262 cases (89.1%) were hospital-acquired candidemias, 27 (9.1%) were health-care associated candidemias, and 5 (1.7%) were community-acquired candidemias. Among underlying conditions or risk factors for candidemia, solid-organ cancer was the most common (40.1%), followed by diabetes (19.7%) and liver disease (10.2%). Variables present at the onset of infection included presence of an indwelling urinary catheter (76.8%) and/or CVC (72.4%), total parenteral nutrition (TPN) administration (46.9%), immunosuppressive therapy (40.8%) and neutropenia (6.1%). One hundred two patients (34.7%) were in the ICU at the time of candidemia, and 162 (55.1%) were admitted with a surgical diagnosis. There were 60 (20.4%) catheter-related candidemia cases. The 30-day mortality rate for this cohort of hospitalized patients was 52.3% (154 of 294 patients).

Patients infected with *C. albicans* were more likely to have solid-organ cancer (45.2% versus 33.3%, *P* = 0.03) or indwelling urinary catheters (80.9% versus 71.4%, *P* = 0.05), and more likely
to have received immunosuppressive therapy (48.8% versus 30.1%, \(P = 0.001\)), compared to patients infected with non-\textit{C. albicans Candida} species. The mortality rate in patients with BSIs due to \textit{C. albicans} was significantly higher than in patients with BSIs due to non-\textit{C. albicans Candida} species (57.7% versus 45.2%, \(P = 0.03\)) (Table 1).

Two hundred fifty-one patients (85.4%) received adequate systemic antifungal therapy for candidemia for a median length of 16 days (range, 1 to 29). Therapy consisted of fluconazole in 136 (54.1%) cases, amphotericin B (conventional or lipidic formulations) in 83 cases (33%), caspofungin in 22 (8.6%) cases, voriconazole in 9 (3.6%) cases, and itraconazole in 2 (0.7%) cases. Therapy was considered inadequate for 43 patients. Of these, 31 patients received antifungal treatment after 48 h of the time that a positive blood sample for culture was drawn, 6 patients (fluconazole-treated) were infected by either \textit{C. krusei} or \textit{C. glabrata} which was found to be resistant to azoles in vitro, and the remaining six patients were never treated.

**Univariate and multivariable analyses.** From the univariate analysis of risk factors for mortality in patients with candidemia, age \((P < 0.001)\), hospital-acquired candidemia \((P = 0.01)\), immunosuppressive therapy \((P = 0.003)\), APACHE III score \((P < 0.001)\), presence of CVC \((P = 0.003)\), infection by \textit{C. albicans} \((P = 0.03)\), biofilm production by overall \textit{Candida} species \((P < 0.001)\), and inadequate antifungal therapy \((P = 0.01)\) were variables significantly associated with increased mortality. In contrast, infection by \textit{C. parapsilosis} was associated with decreased mortality \((P = 0.007)\) (Table 2).

On multivariable analysis, we found that inadequate antifungal therapy (odds ratio [OR], 2.35; 95% confidence interval [CI], 1.09 to 5.10; \(P = 0.03\)), infection by biofilm-forming \textit{Candida} species (OR, 2.33; 95% CI, 1.26 to 4.30; \(P = 0.007\)), and APACHE III score (OR, 1.03; 95% CI, 1.01 to 1.15; \(P < 0.001\)) were independent risk factors for mortality.

**Relationship between mortality and \textit{Candida} species biofilm production.** The mortality rate in patients with BSIs due to biofilm-positive isolates was significantly higher than in patients with BSIs due to biofilm-negative isolates (70% [56 of 80] versus 45.7% [98 of 214]; \(P < 0.001\)).
the patients were stratified for severity of illness, patients infected with a biofilm-forming isolate also had a higher risk of mortality than patients infected with a non-biofilm producer for patients with APACHE III scores less than or equal to 15 (n = 50) (66.7% versus 13.6%; \( P = 0.002 \)) and for patients with APACHE III scores greater than 15 (n = 244) (70.3% versus 54.1%; \( P = 0.01 \)). The relationship between biofilm positivity of *Candida* species isolates and mortality for the 294 patients with candidemia is displayed in Table 3. Among infections by biofilm-producing isolates, only those due to *C. albicans* (\( P < 0.001 \)) or *C. parapsilosis* (\( P = 0.003 \)) correlated with increased mortality. No statistically significant differences in mortality between patients infected by biofilm-forming isolates and patients infected by biofilm-negative isolates were noted for the other *Candida* species. When mortality was analyzed in relation to the amount of biofilm produced by overall *Candida* species isolates, we found that mortality was lowest if isolates were non-biofilm producers (45.8%) and significantly increased to 66.6% (\( P = 0.009 \)) and 75% (\( P = 0.002 \)) if isolates exhibited a low and high biofilm-forming ability, respectively.
DISCUSSION

*Candida* species are now the fourth most common cause of nosocomial BSIs worldwide (30). Variables such as patient age, underlying disease, location in hospital, and antifungal drug exposure may influence the frequency and rank order of *Candida* species causing BSI (28). In this study, the distribution of *Candida* species was similar to reports from other European countries (1, 36, 38), with *C. albicans* being the fungal species most frequently isolated from blood but significant increases found in the prevalence of non-*C. albicans* Candida species invading the bloodstream. An exception is the frequency of *C. glabrata*, which was the fourth most common species in our study but the second most common in Switzerland (22), the United Kingdom (15) and the United States (9). A similar trend was observed in our study for BSI isolates of biofilm-forming non-*C. albicans* Candida species, whose frequency increased compared to biofilm-forming *C. albicans* isolates. The explanation for this observation is not clear and warrants further study, but it is possible that some medical procedures might consistently impact the risk of developing candidemia caused by a fungal isolate capable of forming biofilm over the years.

Candidemia ranks among the infections with highest mortality rates (10). Estimated rates of crude mortality due to candidemia can reach almost 60%, and attributable mortality rates of 49% have been reported in patients with candidemia (8). Candidemia has been associated with mortality rate increases of 10% and 14.5% in hospitalized pediatric and adult patients, respectively (41). The impact of candidemia on mortality suggested a compelling need for clinical prediction rules to identify subsets of hospitalized patients at particularly high risk for candidemia. In accord with these findings, a high mortality rate (52.3%) was also seen in our patient population.

In the multivariable analysis of factors that may influence clinical outcome, we found, not surprisingly, that inadequate antifungal therapy was an independent predictor of mortality. Previous studies have shown that early and appropriate antifungal treatment correlated with improved candidemia outcomes (1, 6). Antifungal resistance was rarely found in our study and was restricted to a few isolates. With the exception of *C. krusei*, 15% of our *C. glabrata* isolates were resistant to
fluconazole. It is interesting to note that 31 (10.5%) of our patients did not receive antifungal therapy within the 48 h after a blood sample was obtained for culture. According to previous observations (6, 26), this finding should induce clinicians to consider the use of empiric antifungal therapy in patients at high risk for candidemia. Our analysis also showed that high APACHE III score was independently associated with an increased risk of mortality, thereby confirming results of previous studies (2, 6). Notably, multiple logistic regression analysis identified infection by biofilm-forming Candida isolates as another independent predictor of mortality. In fact, we found death rates differed significantly between patients infected by biofilm-positive Candida species and biofilm-negative organisms (70% versus 45.7%). Moreover, among patients with low APACHE III scores, the deaths of patients with candidemia caused by biofilm-forming isolates were greater than those of patients with candidemia caused by biofilm-negative isolates.

Our study extends and, in part, confirms the finding of Shin et al. (37) by showing similar results in a retrospective cohort study using a heterogeneous hospital population. Shin and colleagues examined, for the first time, biofilm production among bloodstream Candida species isolates obtained from 101 non-neutropenic patients. They found no significant association between biofilm formation and outcome of fungemia (in terms of cleared or uncleared infection) by C. albicans or non-C. albicans Candida, suggesting that factors besides biofilm formation are involved in clearing Candida from the bloodstream. The small numbers of bloodstream isolates obtained for each Candida species in that study, though, underscored the need for a larger clinical study. Candida species and strain type were shown to affect biofilm formation in vitro (3, 11, 19, 37). Hawser and Douglas (11) demonstrated that isolates of C. parapsilosis, Candida pseudotropicalis, and C. glabrata made significantly less biofilm than C. albicans, which is more pathogenic. The finding that C. albicans isolates consistently produce more biofilm in vitro than non-C. albicans isolates was confirmed recently (19). On the other hand, non-C. albicans Candida species, particularly C. tropicalis and C. parapsilosis, appear to form biofilms readily when grown in SDB medium containing 8% glucose (considered very similar to the in vivo milieu) (37). This capability
might derive from the potential of these isolates to cause candidemia in patients receiving TPN, where the solution administered usually has a high glucose concentration. Of the 59 patients with CVC-related candidemia studied by Shin et al. (37), 46 (78%) received TPN via CVC, and the non-
*C. albicans* *Candida* species recovered most frequently from blood samples was *C. parapsilosis*, which had a high frequency of biofilm production. In our study, *C. tropicalis* was the species with the highest percentage of biofilm positivity (71.4%), whereas only 22.6% of the *C. albicans* isolates tested could form biofilms in high-glucose SDB medium. Similar percentages were shown by isolates of *C. glabrata* (23.1%), and *C. parapsilosis* (21.8%).

Another remarkable finding of our study was the association between biofilm-forming ability of *C. albicans* and *C. parapsilosis* isolates and increased mortality rates for patients with BSI due to these organisms, thus suggesting that the capability to form biofilms may be important in contributing to the virulence of *C. albicans* or enhancing the pathogenic potential of *C. parapsilosis*. However, Hawser and Douglas (11) failed to reveal any correlation between pathogenicity and in vitro biofilm formation in *C. albicans* isolates (all 15 isolates in their study were biofilm producers), even though the authors did not report any criteria or assay to test the pathogenicity of their isolates. Similarly, Shin et al. (37) did not find any significant association between biofilm production and clinical outcome of candidemia caused by *C. albicans*, since only 2 of 30 blood isolates of *C. albicans* in their study were biofilm-positive when tested for the capacity to form biofilms using the same assay as that in the present study. Discrepancies between our results and those of the Shin’s group support the concept that biofilm formation is a stable characteristic of *Candida* strains that varies greatly among clinical isolates, as recently stated by Jain et al. (13).

In this study, we used polystyrene plates to grow biofilms. Although a valid assay for biofilm formation in *C. albicans* based on polystyrene microtiter plates has now been established and standardized (33), it is possible that use of other materials, such those used for indwelling devices including catheters (e.g. silicone elastomer), may give results different from those we obtained here, perhaps because the polystyrene may not reflect exactly the in vivo biofilm formation abilities. In
addition to the substrate material, it is important to note that other environmental parameters, such as substrate preconditioning solutions (i.e., those mimicking physiologic conditions, such as the presence of serum or saliva) and growth media can affect biofilm production. Again, our biofilm assays did not include an initial step, where nonadherent cells are removed after 90 min incubation with the standardized *Candida* suspension (adhesion phase) and adherent cells are incubated for prolonged period in the presence of media (biofilm formation phase). This step would hamper the co-adhesion of planktonic cells to adherent cells and ensure uniform biofilm formation on plastic surfaces (19). In this context, our study has some limitations. However, our analyses showed that the amount of biofilm formation was highly correlated between the two methods we employed to indirectly measure it. This correlation suggested that varying ability exhibited by our *Candida* strains to adhere and grow on polystyrene surfaces was really a reflection of intrinsic physiological differences among the various clinical isolates being compared.

In conclusion, we showed that, together with inadequate antifungal therapy and high APACHE III scores, *Candida* biofilms adversely affect the health of hospitalized patients with candidemia and are thus a significant predictor of mortality. Our findings provide a foundation for future studies examining the correlation between biofilm formation and clinical outcome in high-risk patient populations.

*Includes *Candida guilliermondii* (3 patients), *Candida krusei* (2 patients), and *Candida* spp. (3 patients).
Legends

Figure 1. Annual distribution of Candida species causing BSIs during a 5-year study period.

Figure 2. Annual distribution of biofilm-producing Candida albicans (▲) and non-C. albicans species (□) isolated from BSIs between 2000 and 2004. The amount of biofilm produced was determined by the %T and XTT reduction methods, as described in Materials and Methods.

Figure 3. XTT formazan signal produced by 294 Candida isolates examined for biofilm formation ability. According to the %T results (see the text for details), isolates were classified as non-, low- or high-biofilm producers. Differences in XTT activity among groups were statistically significant ($P < 0.0001$).
