Aichi virus has been associated with acute gastroenteritis in adults and children. Stools were collected from 788 Tunisian children suffering from diarrhea. Aichi virus was observed in 4.1% of cases. The high proportion of monoinfections and the high frequency of hospitalizations support the role of Aichi virus in pediatric gastroenteritis.
Aichi virus was reported in 1989 as responsible of oyster-associated nonbacterial gastroenteritis in a patient in Aichi, Japan (11). This virus is a new member of the Picornaviridae and is assigned to a new genus named Kobuvirus (6, 14). Two genotypes A and B have been described (15). More recently, a third genotype C has been proposed, on the basis of phylogenetic analyses of both 3CD and VP1 sequences (1).

Very few studies report on the epidemiology of Aichi virus and its impact on human health. Its presence in stools collected from nonbacterial gastroenteritis outbreaks, especially due to oyster consumption, has been documented in Japan (12, 15, 16), Germany (4) and France (1). Moreover, the presence of the Aichi virus was reported in oyster samples, during a French event of gastroenteritis occurring after oyster consumption (3). Aichi virus was also found as the etiologic agent of sporadic gastroenteritis in Japanese tourists from Southeast Asia (13). However, this virus was not detected in The Netherlands despite its research for ten years (10). These rare reports on the presence of Aichi virus in diarrheic stools from adults reflect a low incidence of Aichi virus infections. Just as in adults, there has been limited knowledge about the epidemiology of Aichi virus infection in children. Its presence in fecal specimens of children suffering from diarrhea has been demonstrated in several Asian countries (5, 13), in Brazil (4) and in France (1). Nevertheless, despite the low incidence of Aichi virus encountered in sporadic and epidemic cases, several studies of seroprevalence conducted in Japan (12), Germany (4), Spain (Buesa, personal communication 28 Sept 2007) and more recently in France (2) indicated that this virus is quite frequent. The high level of seroprevalence in adults indicates widespread exposure to Aichi virus during childhood.

In a previous paper describing a 2-year study, we reported on the presence of Aichi virus in Tunisian children suffering from gastroenteritis (8). To gain more insight into the epidemiology of the Aichi virus circulating in the pediatric Tunisian population, and to characterize the strains at the molecular level, we expanded the survey to a period of more than four years.

Diarrheic samples were collected from 788 children < 12 years old (74.6% < 2 years old) in Monastir, Tunisia: 408 were collected from January 2003 to April 2007 from hospitalized children within 24 hours of admission (inpatients), and 380 were collected between January 2003 and May 2004 from outpatient children presenting in the dispensaries for gastrointestinal symptoms. The samples were all negative for bacterial pathogens and parasites. Aichi virus was detected by RT-PCR using the primer pair 6261 and 6779 (15) and a Qiagen OneStep RT-PCR kit (Qiagen, Hilden, Germany) to amplify a 519-bp fragment at the 3CD junction. Genotyping was performed by direct sequencing of the PCR products with
the same primers. Phylogenetic and statistical analyses were performed as previously described (8).

Thirty-two (4.1%) samples were positive for Aichi virus. Screening for other viruses showed that group A rotaviruses were predominant (27%), followed by noroviruses (16.2%). Astroviruses, adenoviruses 40/41 and sapoviruses were also detected in 3.6%, 2.3% and 0.8% of stool specimens, respectively. Of the 32 samples positive for Aichi virus, 25 (78.1%) were monoinfections, whereas 3 (9.4%), 1 (3.1%) and 1 (3.1%) were also positive for rotavirus, astrovirus and norovirus, respectively. Moreover, 2 (6.2%) samples were infected by a combination of Aichi virus, rotavirus and astrovirus. Among the monoinfections, Aichi virus was detected in 18 stool samples from inpatients and in 7 specimens from outpatients, which corresponded to ratio of 4.4% and 1.8%, respectively. The monthly distribution of the Aichi virus cases is presented in Figure 1.

Most studies in the literature reported a low incidence of Aichi virus in the pediatric population: 2.3% in Pakistani children (13), 0.9% in French children hospitalized for acute gastroenteritis (1), 3.1% in children from Japan, Bangladesh, Thailand and Vietnam (5). In the Tunisian pediatric population, the frequency of detection of Aichi virus was then relatively higher than usually observed. Aichi virus has been proposed as an etiologic agent of oyster-related gastroenteritis outbreaks (11, 12, 15, 16), but the almost systematic presence of mixed infections with other viruses led to consider Aichi virus an indicator of infection rather than the only causative agent of the gastroenteritis (1). However, the high incidence of monoinfections observed in our study supported the idea that Aichi virus is a pathogenic agent responsible for gastroenteritis, although far below norovirus and rotavirus that are the main agents. Moreover, the presence of Aichi virus in pediatric stool samples suggests that it can be transmitted by other ways than oysters, since young children usually are not consumers of these products. In addition, we observed that monoinfections due to Aichi virus were significantly more frequent among the hospitalized pediatric population than among the outpatients (P=0.04). There is no data in the literature about the implication of Aichi virus in the hospitalization of children with acute gastroenteritis, but our results suggested that this virus could be virulent enough to require hospitalization. However we can not exclude the possibility that other pathogens, unknown, undetected or not tested for, could be responsible for the gastroenteritis.

The phylogenetic analysis of the Aichi virus strains showed that all samples were classified as genotype A and divided into three groups H1, H2 and H3, according to their nucleotide identities (Fig.2). Despite the limited data in the literature, different studies suggested some
geographical distribution of the genotypes. In Germany and France, only the genotype A has been observed (1, 4) and is also predominant in Japan (5, 15). Only the genotype B has been isolated from Pakistani children (15) and was predominant in Bangladeshi children (5). The genotype B was also described in Brazil (4) and Malaysia (15). The epidemiology of Aichi virus in Africa is not yet known. One child hospitalized for gastroenteritis just after returning from a trip to Mali was found positive for a strain of genotype C (1). Additional studies are required to learn about the epidemiology of Aichi virus in Africa, but according to our results, genotype A seems to be predominant in the Tunisian child population.

In conclusion, the high incidence of monoinfections observed and the relatively high frequency of hospitalizations due to Aichi virus infections, support the role of Aichi virus as a causative agent of pediatric diarrhea. However further studies must be conducted notably on controls to check that healthy children are free of Aichi virus.

**Nucleotide sequence accession numbers.** The nucleotide sequences reported here have been deposited in the GenBank sequence database under the following accession numbers: FJ872477 to FJ872508.

The study was partly supported by the CMCU Project (code 04/S0813) and the National Reference Center (NRC) for Enteric Viruses (Dijon, France). We would like to thank the members of the NRC for their technical support.
