Abstract

Hereditary haemorrhagic telangiectasia (HHT) is a disease characterized by arteriovenous malformations (AVMs). Brain abscess is a complication of HHT with AVMs. Literature provides evidence that Enterococcus faecalis can cause endodontic infections. We present the case of a HHT patient who developed brain abscess due to E. faecalis after a dental procedure.
Case Report

A 28-year-old Caucasian woman was presented to our hospital with a 5-day history of visual disturbances. She complained of loss of some part of her normal visual field and especially a defect in her peripheral vision. Her past medical history was significant for a brain abscess, surgically treated 6 years ago (in 2005), on the occasion of which the diagnosis of HHT was made and two small AVMs in the lungs were detected.

On admission, the patient was alert, oriented and afebrile. The neurological examination revealed left homonymous hemianopsia, without decrease in visual acuity. There was no neck stiffness and the fundoscopy was normal. The remaining of the physical examination was remarkable for hypoxemia (SatO₂=90%), mild cyanosis and digital clubbing, as well as sparse telangiectasias on the mucosal surface of her lower lip. No cardiac or extracardiac murmurs were present and there was no tachypnea or complain for dyspnea.

Whole blood count, C-reactive protein and urinalysis were normal except of hemoglobin 16.9 g/dl. Chest X-ray lateral films showed a 10mm in diameter nodular lesion corresponding to one of the patient's known AVMs (Figure 1). Magnetic Resonance investigation (MRI) revealed a hypodense lesion in the right occipital lobe with ring enhancement after contrast administration, exerting mild pressure on the occipital horn of the ipsilateral lateral ventricle (Figure 2). Based on the patient’s history, a brain abscess was strongly suspected and a CT-guided stereotactic aspiration was carried out. Culture of the pus drained yielded Enterococcus faecalis (E. faecalis), while blood cultures were sterile. Cardiac and abdominal ultrasonography showed no site of potential microbial entry. However, additional clinical history elicited on admission disclosed a dental procedure 10 days before the onset of symptoms. The patient was initially treated with ceftriaxone and metronidazole intravenously, followed by moxifloxacin intravenously for 2 weeks and then p.o for 5 more weeks. The patient's course was uneventful and she was discharged asymptomatic 20 days after admission.

Hereditary haemorrhagic telangiectasia (HHT), also known as Rendu-Osler-Weber syndrome, is an inherited autosomal dominant disorder, affecting approximately 1 in 5000 individuals (13). HHT was first described as a familial disease characterized by episodes of spontaneous and recurrent epistaxis, cutaneous and mucosal visible dilated blood vessels (telangiectasias) and visceral arteriovenous malformations (AVMs) usually involving the pulmonary, hepatic, cerebral, spinal and other
circulations (10, 13). These features are the Curacao criteria which remain the mainstay of diagnosis (10). An individual is considered to have a “definite” HHT if three out of four criteria are satisfied, “suspected” if two are present and “unlikely” if only one is present (10, 13). Screening programmes in asymptomatic individuals indicate that pulmonary AVMs affect almost 50% of HHT patients (3). The development of brain abscess is a potential complication of HHT with pulmonary AVMs and can be the initial presentation of it (5). Brain abscess is believed to occur in about 5-10% of patients with HHT (9). Bacteraemias, especially of dental origin, are considered to play a role in the pathogenesis of brain abscess in patients with HHT (11). Moreover, there is evidence that these patients might also exhibit mild immunodeficiency (2).

Brain abscess usually develops from a contiguous focus of infection, most often middle ear, mastoid cells, paranasal sinuses and less often from dental infection and trauma or by hematogenous dissemination (7). HHT is a predisposing factor leading to hematogenously acquired brain abscess which is almost always observed in patients with coexisting pulmonary arteriovenous malformations, perhaps by allowing septic emboli to cross the pulmonary circulation without capillary filtration or by bacterial seeding of an ischemic portion of the brain after paradoxical sterile emboli have formed (13). Cerebral hypoxia and polycythemia due to right-to-left shunt are considered to enhance bacterial growth (13). HHT patients are expected to experience prolonged bacteremic periods, since the shunt provided by AMVs abolishes the exposure to the capillary bed reticuloendothelial cell system (12).

Although dental infection is considered to be an uncommon source of hematogenous dissemination resulting in the formation of brain abscess in the general population (7), many cases in the literature report the isolation of components of the normal oral flora from the brain abscess of HHT patients. In a recent study, Shovlin et al, confirmed that the majority of organisms isolated from brain abscess aspirates of HHT patients were microaerophilic and anaerobic bacteria commonly met in endo and periodontal infections. Moreover, many of the HHT patients seemed to have experienced identifiable events, known to be associated with bacteraemia in the weeks preceding their abscess, particularly dental work, further confirming the pathogenic link between oral bacteria and HHT-associated brain abscess (11). For the above mentioned reasons and despite the controversies concerning the use of prophylactic antibiotics even for the prevention of bacterial endocarditis, antibiotic...
prophylaxis is still suggested for HHT patients with AVMs prior to dental procedures (12).

\textit{E. faecalis} is an infrequent causative agent of brain abscess. It is usually a nosocomial pathogen and its presence in CNS, rarely if ever as a cause of meningitis, has been associated with anatomic defects, prior neurosurgery and trauma or high-grade bacteraemia and immunodeficiency (8). Common portals of entry for enterococcal bacteraemia are the urinary tract, intra-abdominal and pelvic sepsis (4, 8). However, recently, literature provides evidence that due to its ability to produce biofilms, \textit{E. faecalis} is often involved in endodontic infections (4), rendering dental work a potential portal of enterococcal bacteraemia.

Our patient’s brain abscess could have been secondary to a dental procedure for the following reasons: The patient had untreated AVMs. She was subjected to an interventional dental procedure 10 days before admission without having received antibiotic prophylaxis. \textit{E. faecalis}, which is considered to be a causative agent of endodontic infections, was isolated from the abscess pus while no other site of enterococcal entry was apparent. A literature review revealed three cases of brain abscess from the pus of which \textit{E. faecalis} was isolated (1, 6, 14). However, in each case a predisposing factor such as prior neurosurgery (1), enterococcal bacteraemia due to aspiration pneumonia (6) or urinary tract infection (14) was present. To the best of our knowledge this is the first report of a brain abscess due to \textit{E. faecalis} in a HHT patient without any site of enterococcal entry apart from a dental procedure.

In conclusion, our patient’s case is both unique and instructive. It identifies interventional dental work as a potential source of \textit{E. faecalis} seeding, highlighting the fundamental role of \textit{E. faecalis} as cause of endodontal infections. Also, it demonstrates that antibiotic prophylaxis seems to be necessary for all bacteraemia-causing procedures in patients with HHT and AVMs.
